WDV341 Intro to PHP

1-2: Download Git Client & Create a Repository account

Within Git, users can expect to encounter several terms: *version control software*, *add*, *commit*, *push*, *pull*, and *clone* to name a few. Github uses a free, open-source distributed **version control software**, which is a practice of tracking a codebase's history on a developer's setup. The biggest difference between a centralized and a distributed version control software is that the distributed vc software allows a user to work offline.

Add and **commit** are terms that go hand-in-hand in Git. Add is the first step in the process of uploading changes to a repository. A user will “add” whatever changes are happening to a *staging area* before they commit the changes, thereby uploading them to the repository. **Push** is the next step of “pushing” those changes out to all project collaborators by making it available on remote repositories instead of just the local one.

When a user wants to update their local repository with the changes from a remote repository, they can use the **pull** command to bring those changes from remote to local. Finally, users can use the command **Clone** to duplicate a repository locally.
